LAKE SUPERIOR LIMNOLOGICAL DATA, 1951-57

Explanatory Note

The series embodies results of investigations, usually of restricted scope, intended to aid or direct management or utilization practices and as guides for administrative or legislative action. It is issued in limited quantities for the official use of Federal, State, or cooperating Agencies and in processed form for economy and to avoid delay in publication.

United States Fish and Wildlife Service Special Scientific Report--Fisheries No. 297

Washington, D. C.
April 1959

ABSTRACT

Physical, chemical, and plankton data collected by the M/V Cisco (U. S. Fish and Wildlife Service) in Lake Superior in 1952 and 1953, temperature data obtained by the M/V Williams (U. S. Lake Survey) in 1956 and 1957, and temperatures recorded by thermographs during 1951-1957 are presented with limited interpretation.

Ion concentrations were low and varied little vertically, seasonally, or from area to area. A relatively high plankton abundance along the south shore from the Apostle Islands to Grand Marais, Michigan, was related to relatively high phosphorus concentrations. Much of this phosphorus may enter the lake at Duluth. If so, it must be transported by an inshore current. This movement furnishes evidence of a general counterclockwise circulation as indicated by drift cards released in 1953.

LAKE SUPERIOR LIMNOLOGICAL DATA 1951 - 1957

The Great Lakes have long been a challenge to limnologists and freshwater hydrographers. Even now, only modest advances have been made in exploring this largest system of freshwater lakes in the world (Smith 1957). Lake Superior, the largest freshwater lake of the world, has received less attention than any other of the Great Lakes, probably because of the problems of special operating and equipment imposed by its great area (31,820 square miles) and depth (maximum, 222 fathoms). Only recently has this formidable equipment requirement been met in operations of specially constructed Great Lakes research vessels by the U. S. Fish and Wildlife Service and U. S. Lake Survey, and of refitted existing vessels by the University of Minnesota (Ruschmeyer, Olson, and Bosch 1957).

Data presented here were gathered during the operations of the M/V Cisco (Great Lakes Fishery Investigations, U. S. Fish and Wildlife Service-see Moffett 1954 for description) in 1952 and 1953, and the M/V Williams (U. S. Lake Survey) in 1956 and 1957. Also included are surface temperatures obtained from thermographs operated by the staff at the Marquette station of the Great Lakes Fishery Investigations in 1951-1957. This report lists limnological data from these sources, without extensive interpretation, to make the records available to other interested agencies.

OPERATIONS OF M/V CISCO

The Cisco was used in an exploratory survey of Lake Superior in August 1952 to collect data for planning the full-season (May-October) study of 1953. After lake trout populations of Lakes Michigan and Huron were depleted following invasion of the sea lamprey (Hile 1949; Hile, Eschmeyer, and Lunger 1951), only Lake Superior remained as a source of the life-history information vitally needed for planning future rehabilitation programs. Since the early life history was least known and most important in establishing a planting program, it received primary attention in the study. Operations of the vessel were guided by requirements for collection of data on lake trout and hence were concentrated in the inshore nursery areas for this species.

Restrictions imposed by the lake trout study limited but did not preclude the collection of extensive limnological data. Temperature measurements with a bathythermograph were made at frequent intervals along routes traveled in 1952, and limited physical and chemical data were obtained at selected hydrographic stations. Plans for 1953 provided for routine collection of temperature and chemical data at regular intervals between ports of call and fishing locations. Hydrographic stations were established along these transects as time and conditions permitted. Where hydrographic stations were located on routes of travel or at important fishing locations, repeat visits were possible.

The 3-week cruise in August 1952 covered the south shore of Lake Superior east of the Keweenaw Peninsula, Keweenaw Bay, and most United States waters (north and south shores including Isle Royale) from Keweenaw Peninsula to the Apostle Island region (fig. 1). During the 1953 season the lake was covered from the Two Harbors-Port Wing line in the west to the eastern extremity of the lake (figs. 2, 3). The lake was divided roughly into west, central (Keweenaw-Isle Royale area), and east sections. These areas were covered in approximately 2-week cruises on the following schedule:

| Cruise | Period (1953) | Section |
|--------|------------------------|---------|
| I | May 3-13 | Central |
| П | May 21-June 4 | West |
| Ш | June 11-23 | East |
| IV | July 1-14 | Central |
| V | July 22-August 14 | West |
| VI | August 12-25 | East |
| VII | September 2-14 | Central |
| VIII | September 27-October 6 | Central |
| IX | October 14-25 | Central |

Sections were not given well defined boundaries and some overlap usually occurred in coverage of adjacent sections in succeeding cruises. Restriction of Cruise VIII to the central section was necessitated by adverse weather and Cruise IX was largely devoted to sampling juvenile, and to tagging adult lake trout between Marquette and the Keweenaw Peninsula.

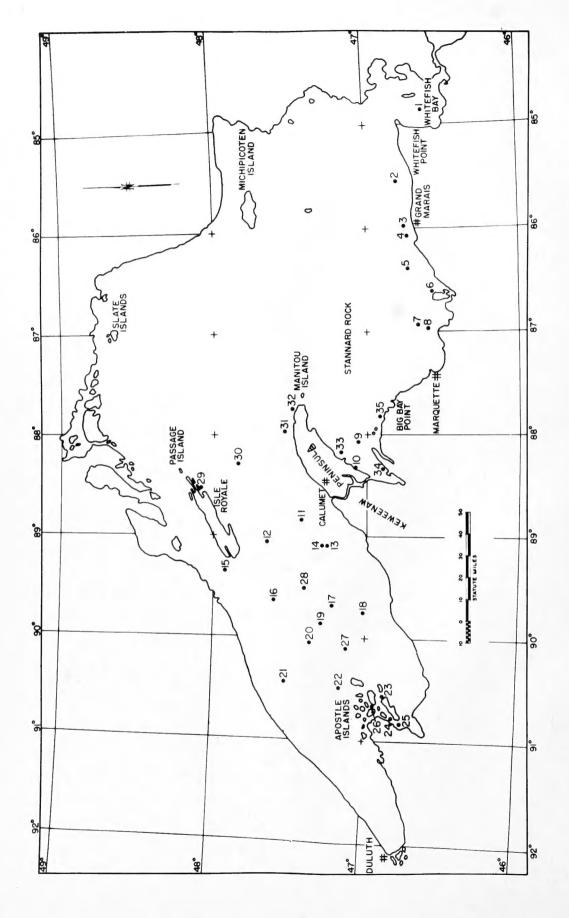

Figure 1. -- Hydrographic stations of the M/V Cisco, 1952.

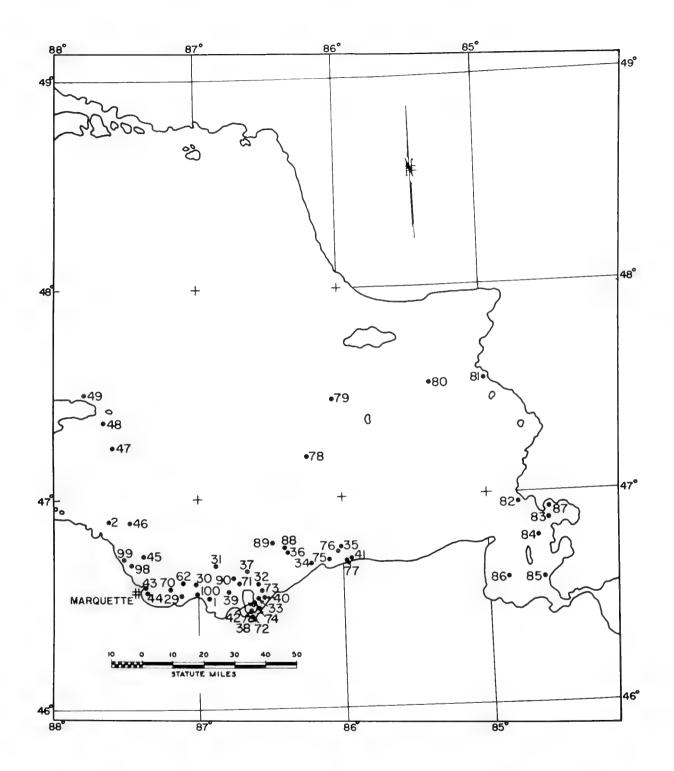

Figure 2. --Hydrographic stations in eastern Lake Superior, M/V $\underline{\text{Cisco}}$, 1953.

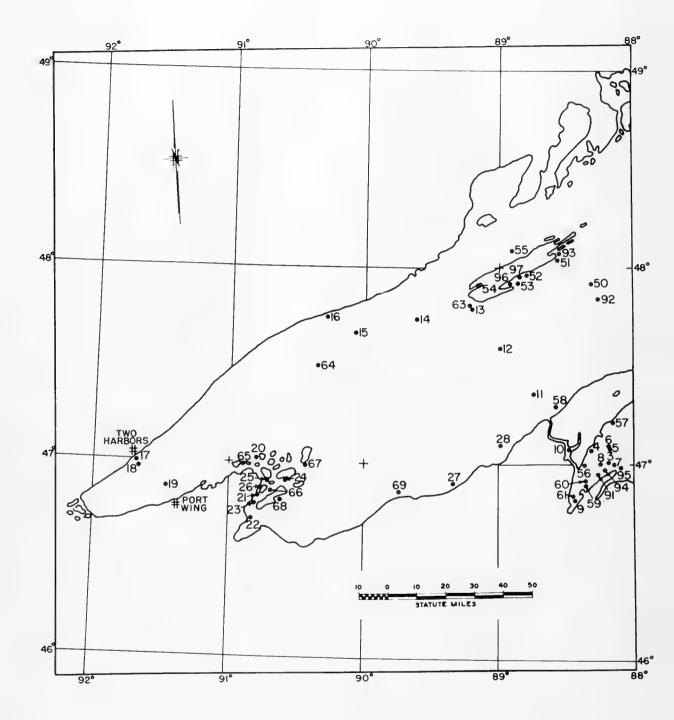

Figure 3.--Hydrographic stations in western Lake Superior, M/V Cisco, 1953.

Stations were numbered consecutively throughout the operating period each year and usually when a station was visited more than once in a year it retained its original number. As a rule, hydrographic stations were established at fishing locations, and at intervals between fishing stations and ports of call as time and conditions permitted. Temperature records at hydrographic stations were made with bathythermographs and with reversing thermometers attached to Nansen bottles. Surface temperatures were determined by lowering a resistancethermometer bulb just below the surface beside the ship or by immersing it in a bucket of freshly collected lake water. After Cruise II of 1953, surface temperatures were also taken from a resistancethermometer bulb inserted in the ship's sea chest which has an intake about 5 feet below the waterline.

Water for chemical analysis was collected with Nansen bottles. Sampling depths varied according to the temperature profile. When the water was homothermous samples were taken at the surface and bottom, and sometimes at intermediate levels depending on the depth. In areas of thermal stratification, samples were collected at the surface and bottom, and in the vicinity of and below the metalimnion.

Secchi-disc readings, surface-plankton tows, and a sample of bottom fauna were usually taken at each hydrographic station. Bottom fauna samples and bathythermograph casts were usually made in connection with fishing operations.

Bathythermograph casts were made at approximately 5-mile intervals between ports and between fishing and hydrographic stations. After Cruise II, 1953, surface-water samples for chemical analysis were usually collected with each bathythermograph cast. These samples were collected with a clean galvanized bucket that was used for no other purpose, and care was taken in filling sample bottles to avoid contamination.

"Drift cards" (postal reply cards sealed in polyethylene envelopes) were released at a few selected stations during Cruise IV, 1953. Limited studies in Green Bay, Lake Michigan, in 1952 revealed that

only a small percentage recovery could be expected, so single releases of about 500 to 1,000 cards were made at one location.

Meteorological conditions were recorded routinely at frequent intervals in the ship's log, and on station log sheets each time a hydrographic or fishing station was visited. Observations included wind direction and velocity, sea state, barometric pressure, sky cover, visibility, and general weather conditions (table 1). Data on wind direction and velocity are approximate, since an anemometer was not used.

Investigations conducted with the <u>Cisco</u> were under the general supervision of James W. Moffett, Chief, and Ralph Hile. Assistant Chief, of the Great Lakes Fishery Investigations, U. S. Fish and Wildlife Service. Vessel operations were supervised by Stanford H. Smith. Paul H. Eschmeyer planned the lake trout study and assisted materially in organizing other phases of the Lake Superior program.

Vernon Seaman served as captain of the <u>Cisco</u> in 1952 and during Cruises I and II, 1953. Leo F. Erkkila acted as captain-biologist in Cruise III, 1953, and Clifford L. Tetzloff served in this capacity during subsequent cruises. Clifford LaLonde was engineer and John Blanchard fisherman-deckhand during the entire operation.

Paul H. Eschmeyer, Stanford H. Smith, and LaRue Wells were in charge of field operations during different cruises. Others who served as scientists aboard the Cisco in Lake Superior were Joseph Beil, Howard Buettner, Daniel Garn, Willis Glidden, Carl Jacoby, and Richard Ryder.

Several people from other organizations gave valuable assistance in addition to undertaking special studies of their own. Russel Daly of the Wisconsin Conservation Department served on the vessel to collect data on smelt of the Apostle Island area during parts of Cruises II and V, 1953. James H. Zumberge (Cruises V and VII, 1953), and James T. Wilson (Cruise VII, 1953) of the Department of Geology, University of Michigan, conducted exploratory core sampling and underwater photography from the Cisco. William Hazen made special plankton collections

during Cruises V and VI, 1953, under the auspices of the Great Lakes Research Institute, University of Michigan.

OPERATIONS OF M/V WILLIAMS

Work in Lake Superior by the U. S. Lake Survey dates back to 1855, when field parties commenced the original hydrographic survey of the lake. The first navigation chart of Lake Superior was published in 1858.

Starting in 1900, hydrographic surveys were performed intermittently as required to keep the charts up to date, to supply detail in the more hazardous places, and to investigate reported dangers to navigation.

In 1929, a survey of the offshore waters of the lake was undertaken with soundings (by line measurements) spaced 3 miles apart. This survey discovered Superior Shoal which is a shallow area with a least depth of 21 feet located in Canadian waters 39 miles south by west from the Slate Islands. When this area was swept for least depth in 1941, four peaks were found in an area of about 2 square miles with 21, 28, 30, and 46 feet of water over them and with relatively deep water between.

A resurvey of the deep water of the lake was commenced in 1956 with recording echo sounders and Shoran, an electronic system for accurately positioning the surveyship the M/V Williams. The sounding lines were spaced 1-1/2 miles apart and all of the deep waters were sounded west of a line from Passage Island through Manitou Island, to Stannard Rock, to Big Bay Point (fig. 4).

The following year, the survey was continued in all the deep waters east of the 1956 work area except for a section 30 miles wide adjacent to the south shore from Marquette to Whitefish Point (fig. 4). Because of the limited range of Shoran, the vast expanse of waters in the eastern portion of the lake made its use impracticable. An Electronic Position Indicator system--commonly known as EPI--which is slightly less accurate but has a much greater range, was loaned to the Lake Survey

by the U. S. Coast and Geodetic Survey and used to locate the soundings. The sounding lines were again 1-1/2 miles apart in most of the area covered. A total of 18,540 lineal miles of sounding and 12.3 square miles of sweeping on shoal areas were recorded in these 2 years of operation.

Surface temperature readings have been observed and recorded for many years in conjunction with the sounding operations. The surface temperatures were taken hourly during working hours when the surveyship was under way. In addition, subsurface temperatures, obtained by bathythermograph, were taken in 1956 and 1957 by the M/V Williams. The bathythermograph observations were taken at approximately 2-hour intervals, sea and weather permitting, while the ship was under way along the designated sounding lines (see figs. 5 and 6 for the distribution of these observations). Air temperatures also were recorded each time the water temperature was measured.

The bottom was sampled, primarily to determine the character of the bottom for anchoring, each time the ship was anchored.

Field work still needed to complete the revision of the charts of Lake Superior is as follows: (1) offshore sounding adjacent to the south shore from Marquette to Whitefish Point; (2) inshore sounding, including such sweeping operations as may be required, along selected portions of the American shore of the lake; (3) a complete hydrographic survey of the American waters of Whitefish Bay; (4) survey of an area between Isle Royale and the north-shore mainland.

The 1956 hydrographic survey of Lake Superior, on which Shoran was used for positioning, was conducted by G. P. Schreiber, Civil Engineer, --assisted by 12 others--under the direction of: Colonel E. J. Gallagher, C. E., U. S. Army, District Engineer; W. R. Laidly, Chief Technical Assistant; and G. E. Ropes, Chief, Charting and Geodetic Branch.

In 1957, the EPI-controlled survey in Lake Superior was conducted by F. Wells Robison, Chief, Charting and Geodetic Branch, --assisted by 11 others--under the direction of: Colonel E. J. Gallagher, C. E., U. S. Army, and Colonel E. H. Lang, C. E., U. S. Army,

Figure 4. -- Area of operations for the M/V Williams, 1956 and 1957.

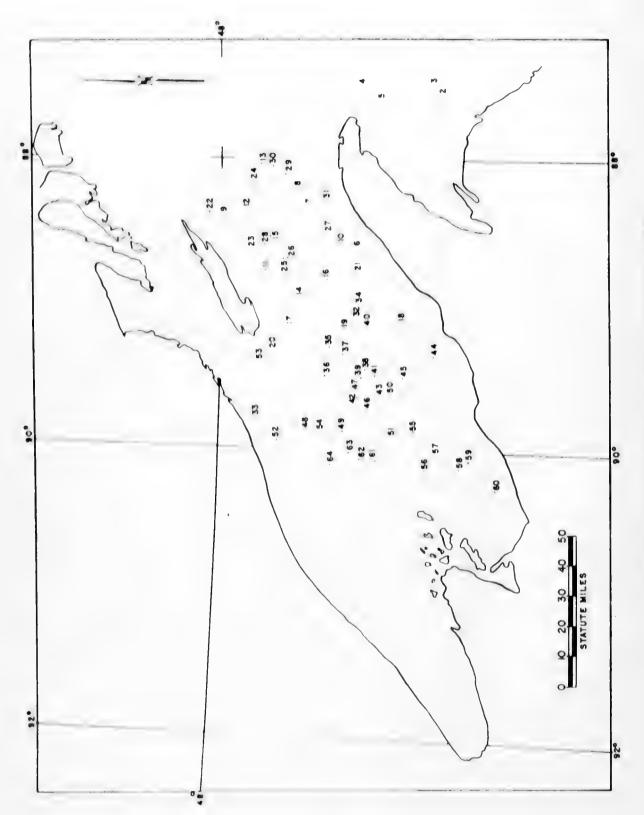

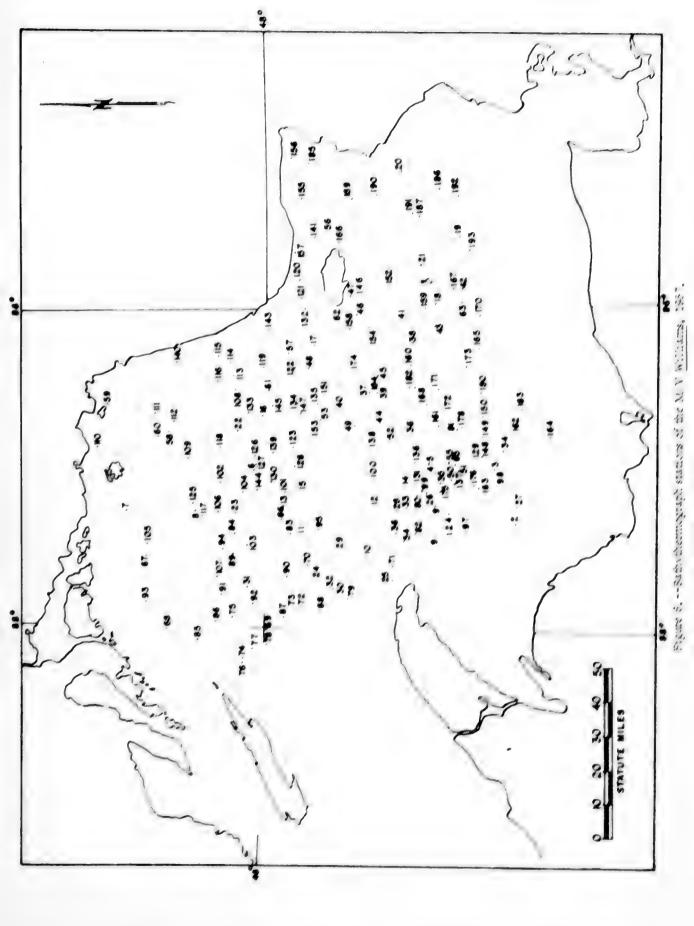

Figure 5. -- Bathythermograph stations of the M/V Williams, 1956.

District Engineers; and W. T. Laidly, Chief Technical Assistant.

Constantine Ben assisted in integrating U. S. Lake Survey data with U. S. Fish and Wildlife Service data in this report.

THERMOGRAPH RECORDS

Thermograph data are from instruments installed by the U. S. Fish and Wildlife Service at: the Lake Superior and Ishpeming Railroad ore dock, Marquette, Michigan, in 1951; Stannard Rock lighthouse in 1952; and the wellhouses of the Marquette water plant (1955) and the Calumet and Hecla water plant (1953). All implements were standard Taylor recording thermographs with 7-day spring-driven clocks and stainless-steel thermal elements.

Leo Erkkila, in charge of the sea lamprey control program of the U.S. Fish and Wildlife Service, was responsible for making the installations and supervised the collection of thermograph data.

EXPLANATION OF DATA

Temperature data

Bathythermograph data of the Great Lakes are well suited for presentation in tabular form. Almost without exception the water is nearly homothermous or there is a well-defined metalimnion (the stratum in which the greatest change in the vertical temperature gradient occurs). The temperature traces can be represented with reasonable accuracy by the surface and bottom temperatures under homothermous conditions, and by temperatures at the surface, top and bottom of the metalimnion, and at the bottom when the water is stratified. Oceanographers have not found it practical to present bathythermograph temperatures in tabular form because of the usual lack of well-defined temperature zones and the general variability of temperature gradients.

Temperatures from bathythermograph traces were read from 3- by 5-inch photographic enlargements of the grid and superimposed trace. These prints are on file at the Ann Arbor office of the Great Lakes Fishery Investigations. Values for each bathy-

thermograph were adjusted by the mean deviation of the temperature from the comparable bucket (or sea chest intake) temperature so that values of different instruments and for different cruises would be comparable. Bathythermographs used on the Cisco were calibrated once during each cruise and at the end of the operating season according to a procedure given by U. S. Hydrographic Office Publication No. 607 (1955). The accuracy obtained by this procedure is better than $\pm 0.3^{\circ}$ C. The reversing thermometers were calibrated by the Engineering Research Institute, University of Michigan. Corrections were only calculated to 0.1° C. Therefore, temperatures taken by these instruments are recorded to the nearest 0.1° C.

Some discrepancy occasionally occurred among reversing thermometer, bathythermograph, and bucket temperatures. There are several explanations for these disagreements: error in depth of reversing thermometers; hysteresis of the bathythermograph; and human errors in reading and recording data. Also, reversing thermometer and bathythermograph lowerings usually were not made simultaneously.

Bathythermograph slides obtained from the U.S. Lake Survey were studied in the same manner as those from the Cisco. The depth range of the Survey bathythermographs was 0-450 feet. Calibrations of the instruments were not made until the close of the 1957 season at which time it was discovered that the bathythermograph used in 1957 functioned improperly below 2.2° C., consequently temperatures below this figure have not been recorded for that year. A few other slides were discarded because the traces had been partially obliterated. The recorded temperatures are probably accurate to + 0.7° C.

Thermograph temperatures at the four installations were for the following depths:

| Lake Superior and Ishpeming Railroad ore dock | 15 feet |
|---|---------|
| Stannard Rock lighthouse | 16 feet |
| Marquette water plant | 55 feet |
| Calumet and Hecla water plant | 12 feet |

Daily maximum and minimum temperatures were recorded to the nearest ${}^{\circ}F_{\bullet}$. These readings were converted to the nearest 0.1° C_{\bullet} in this report. The temperatures given in tables 19-31 can be considered accurate to \pm 0.5° C_{\bullet}

Chemical data

Dissolved oxygen, pH, and some specific conductance determinations were made in the field. Other analyses were made in the laboratory at Ann Arbor, Michigan. A citrate bottle was used in 1952 to keep samples for laboratory analyses. In 1953 water samples for laboratory analysis for each collection were placed in four 4-ounce bottles--2 glass and 2 polyethylene. One each of plastic and glass was frozen. Water for total-phosphorous analysis (unfrozen glass) was preserved with chloroform.

<u>Dissolved oxygen. -- The unmodified Winkler</u> method was used. Samples were taken directly from Nansen bottles and fixed immediately.

pH. --Determinations were made with a Hellige color comparator. Samples were taken directly from Nansen bottles and analyzed immediately.

Total alkalinity. -- Determinations were by electrometric titration with a Beckman Model G pH meter. A 100-ml sample was titrated with 0.02n H₂SO₄ to the HCO₃ endpoint (pH 4.4). Results are given in ppm of calcium carbonate. Samples collected in citrate bottles were used for this analysis.

Calcium and sodium. -- A Beckman DU spectrophotometer with a flame attachment using an oxyacetylene flame was employed for sodium (wave length 589 mu, slit width 0.2 mm, sensitivity 9) and calcium (wave length 622 mu, slit width 0.4 mm, sensitivity 9) determinations. Water collected in polyethylene bottles (unfrozen) was used.

Magnesium. --A Fischer AC electrophotometer (3 ml cell and 525 mu filter) was used for colorimetric magnesium determination (American Public Health Association 1946). A fresh solution of titian-yellow was made up daily. A new standard curve was made each day to give added accuracy. Unfrozen water from polyethylene bottles was used.

Silica, --Determinations were made by the molybdate colorimetric method (American Public Health Association 1946) with a Fischer AC electrophotometer (23 ml cell and 425 mm filter). Unfrozen water stored in polyethylene bottles was used.

Ammonia nitrogen. -- The sample, previously frozen in a polyethylene bottle, was thawed in running water and brought to room temperature. One ml of Nessler reagent was added to 60 ml of the sample in a 150 ml beaker and mixed. After 1/2 hour, color development was measured with a Fischer AC electrophotometer (60 ml cell and 425 mu filter). Ammonium chloride solution was used as a standard (American Public Health Associates 1946). Tests indicated that various interfering substances were not present in sufficient quantities to make it necessary to follow procedures for their removal (Ellis, Westfall, and Ellis 1948).

Total phosphorous. -- Determinations were made by a modification of the method developed by Harvey (1948). A 50 ml portion of the water sample preserved with chloroform in a glass bottle was placed in a 60 ml flask and dried in an ovenat 100° C. to facilitate the acid-digestion process. After the addition of 0.5 ml of 40-percent sulfuric acid, the flask, covered with a 30 ml beaker, was placed in an autoclave for 7 hours at 25 pounds pressure. The sample was cooled to room temperature and brought up to 25 ml with double-distilled water, and 1 drop of a solution containing 0.25 gm of stannous chloride and 1 ml of concentrated hydrochloric acid in 10 ml of double-distilled water was added. Maximum color development, taking approximately 5 minutes, was measured by a Fischer AC electrophotometer (23 ml cell and 650 mu filter). Usually 35 samples were placed in the autoclave at one time, and a series of standards was always included. Values for samples in each batch were determined on the basis of the standards run with them. Molybdate and stannous chloride solutions were made up fresh each day.

Specific conductance. -- Resistance measurements (ohms) were made with a glass dip-cell and an Industrial Instruments Type RC-16B-1 conductivity bridge. Values recorded for hydrographic stations are from determinations made aboard the Cisco; all others were made in Ann Arbor on samples from polyethylene bottles. Resistance was converted to specific conductance in mhos/cm x 10⁶ at 18°C (K 18) by the following formula:

$$\underline{\underline{K}}_{18} = \underline{\underline{R}_{t} (1 + \underline{c} \underline{\Delta}_{t})}$$

Where \underline{R}_{t} is the measured resistance, \underline{c} is the temperature coefficient of conductance at \underline{t} , and $\Delta \underline{t}$ the difference in temperature between 18° C. and temperature of test measurement.

The determinations for calcium, magnesium, nitrogen, sodium, phosphorus, and silica content show that not only are the concentrations of the various chemicals very low, but the variation in concentration is slight with time as well as from one area to another. In fact, the ratio of calcium, magnesium, and sodium (12:3:1) varied little among seasons and areas of the lake. Few freshwater lakes have this consistency in chemical content. Concentrations of calcium were so uniform from area to area during most of the year, except spring, that the analyses for this element were of little value for identifying water masses. The same was true in some degree for elements other than phosphorus and specific conductance. Consequently, it was necessary to consider several measurements as well as other factors in identifying water masses.

Concentrations of all chemicals as well as plankton were usually low in the central open-lake area. Waters along the north shore from Isle Royale to Duluth had similar characteristics. This similarity may have been due to a counterclockwise current that carried open-lake water into the western end of the lake (Ruschmeyer, Olson, and Bosch 1957). The phosphorous content of the water increased slightly, but significantly after it had flowed past Duluth. These slightly higher phosphorous concentrations occurred in all of the water samples collected along the south shore from Duluth to the Apostle Islands.

The dry weight of plankton per cubic meter in the Apostle Island region was 4 to 5 times greater than at stations within the western arm of the lake. Perhaps the increase in phosphorous, as well as other nutrients from wastes discharged into the lake near Duluth, was responsible for this greater abundance of plankton.

Plankton data

All of the 1952 and most of the 1953 plankton collections were made by Clarke-Bumpus samplers

with No. 10 mesh (aperture 0.158 mm) nets. A few samples were taken in 1953 with No. 20 mesh (aperture 0.076 mm) nets. Horizontal tows usually were made at the surface, although a few were at greater depths. The Clarke-Bumpus samplers were calibrated by towing them a known distance. A few vertical tows were made with a 1/2-meter, No. 20 mesh net in 1953.

The wet volume, and dry, ash, and organic weight were determined for plankton samples collected in 1953. Wet volume was determined by measuring the total volume of the sample and subsequently allowing the plankton in a 10 ml subsample to settle out in a graduated centrifuge tube. The dry, ash, and organic weights of 10 ml portions were obtained by the method described by Welch (1948). The data were multiplied by a factor, determined by the flow of water through the nets, so that all measurements are recorded in milliliters or milligrams per cubic meter of water.

These data have certain limitations that restrict interpretation. Surface tows alone are unreliable for a study of seasonal abundance, and sampling at any one station was not extensive enough to allow suitable comparison of one area with another. Nevertheless, certain conclusions can be drawn which may serve as a guide to future studies in Lake Superior.

If the standing crop of plankton can be considered as indicative of productivity, it may be concluded that the area southeast of the Keweenaw Peninsula and east to Grand Marais, Michigan, is 2 to 3 times more productive than the open-lake area northeast of the Peninsula. Other areas of comparable productivity are the waters of the Apostle Islands and the littoral zone along the northwest shore of the Keweenaw Peninsula.

The dry-weight data for the area southeast of the Keweenaw Peninsula indicate two plankton maxima in this region during 1953, one in early summer and another in early fall. The smallest concentrations occurred in May.

Samples collected at the surface and from various depths at 8 stations showed that during daylight the

maximum concentrations of plankton usually occurred between 9 and 22 meters--2 to 25 times more than at the surface. A few evening collections indicated a reversal of this situation; after sunset, plankton concentrations were greater at the surface than at greater depths.

The high concentrations of plankton among the Apostle Islands, in the littoral current flowing east along the northwest shore of the Keweenaw Peninsula, and immediately east of the Peninsula indicate that the productivity of the area east of the Peninsula may be dependent to a degree upon the nutrients moving in this littoral current from the vicinity of the Apostle Islands.

The relatively high chemical content and plankton concentrations along the south shore east of the Keweenaw Peninsula are evidence of a littoral current flowing easterly. Drift-card returns from this study, as well as those of Ruschmeyer, Olson, and Bosch (1957), suggest that a counterclockwise current usually exists in the eastern basin. Occasionally, openlake waters may be shifted onto the south shore by appropriate wind action. When this movement occurs a large mass of the littoral water must be carried into the open lake by the counterclockwise current. Movements of this type may account for the occurrence of a water mass with the characteristics of littoral water (higher conductivity and plankton) in midlake at station 78 during Cruise V. This littoral current may continue on to the east shore of Whitefish Bay, since water with similar characteristics was found along this shore.

Drift-card studies

In July 1953, 4,470 drift cards similar to those developed by Olson (1951) were released in the vicinity of the Keweenaw Peninsula and Isle Royale, Michigan (table 8; figs. 7-12). By December 1,1957, 363 (8.1 percent) of the cards had been returned; 320 (7.2 percent) were returned in 1953.

Nearly all cards that were returned showed some evidence of exposure to moisture and a few were so badly soaked that the cards had disintegrated within the plastic envelopes. That water-filled

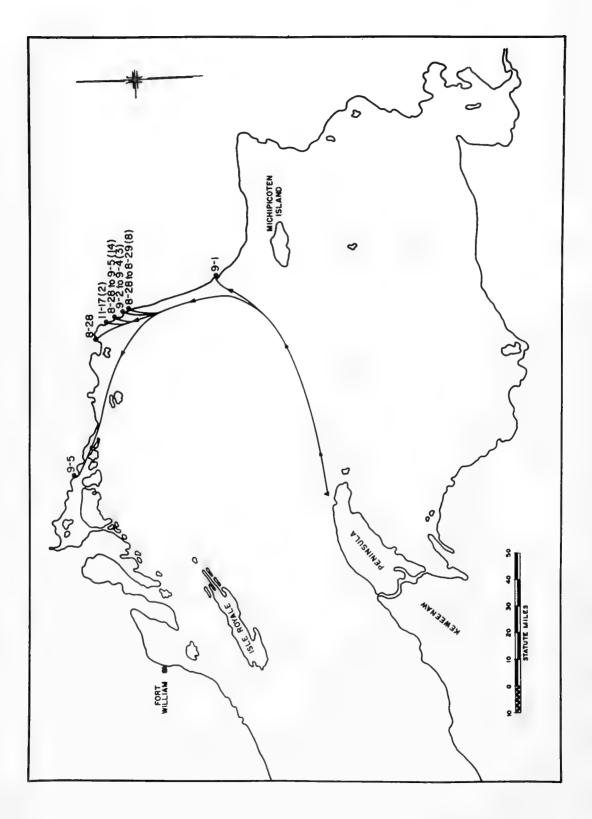

envelopes do sink was demonstrated by several recoveries from the bottom in the clear water around Isle Royale where cards were retrieved from depths up to 10 feet. It must be assumed, therefore, that many envelopes took on sufficient moisture to sink in areas where they could not be recovered.

A faulty seal on some envelopes contributed to the penetration of water. When envelopes were gently agitated in a "squirrel cage" photographic print washer for several days, some leakage occurred in nearly all of them even though they showed no signs of abrasion. Pinhole perforations around the seal could be detected in envelopes that leaked badly. The abrasion of envelopes reaching shore certainly tended further to aggravate leakage. These factors must have contributed markedly to the relatively low recovery rate.

Drift missiles floating at or near the surface must be influenced predominately by the movement of uppermost water. This layer is in turn strongly affected by the wind, and a good correlation of water movement with wind direction and velocity should be expected. Plastic envelopes used in this study float on the surface film when first released, but tend to drift in the upper 1 or 2 inches of water when the plastic ceases to shed water, or if moisture seeps into the envelope. The tendency to float just below the surface film is increased with increases in wind velocity and wave action. Direct observations and experimental releases of drift cards in 1954 (in Lake Michigan) have demonstrated that, when floating on the surface film, they can be moved rapidly on the surface film by light breezes, and that they can cover considerable distances in a short time under relatively calm conditions.

Wind conditions at Fort William, Ontario, on the north shore of Lake Superior are given in figure 13. The wind track is plotted after the method used by Fry (1956).

The varied influence of winds upon cards in plastic envelopes floating on, in or just below the surface film, and under different sea conditions, undoubtedly was important in dispersing them. The wind must also have affected their speed and direction

of movement and long dashes an alternative path. Numbers beside recovery points show period in which cards were recovered (month and Figure 7. --Recovery points of drift cards released at station 48 on July 3, 1953. Triangle indicates point of release. Solid lines show possible paths day) in 1953 and number of cards in parentheses. Short dashes show water movements demonstrated by other information (see text),

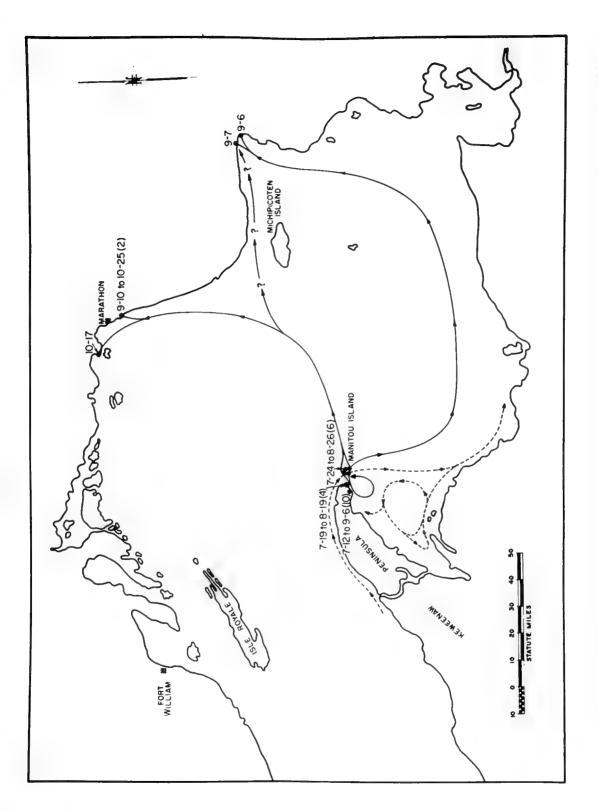

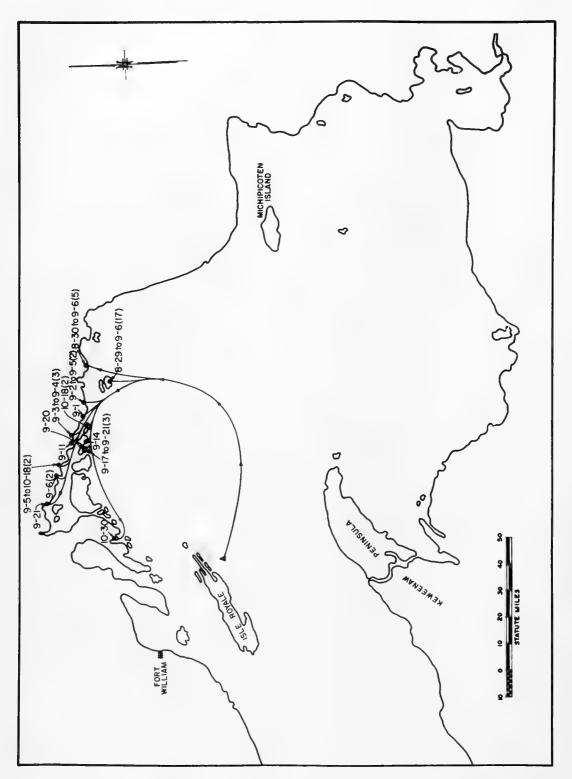

Figure 8. --Recovery points of drift cards released at station 49 on July 4, 1953. Triangle indicates point of release and solid lines show possible paths of movement. Numbers beside recovery points show period in which cards were recovered (month and day) in 1953 and number of cards in parentheses.

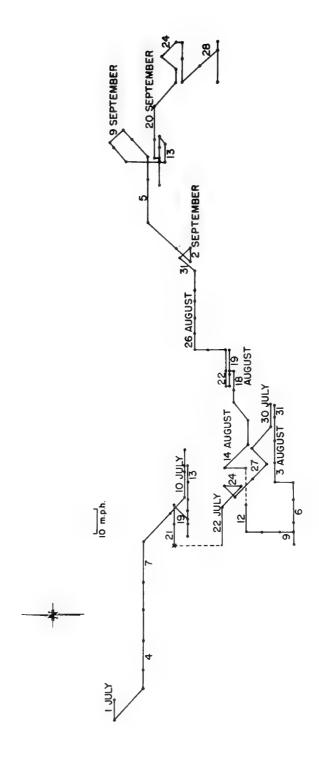

Figure 13. -- Wind track based on records at Fort William, Ontario, Canada, July 1 to September 30, 1953.

of travel. In the period shortly following release, cards may have been more responsive to changes in wind direction than to the direction and velocity of surface-water movements. Movements of these cards can therefore be interpreted as only rough approximations of surface-water movements. Despite their shortcomings as current indicators, some speculation may be permitted about the possible circulation patterns that may have influenced the drift of cards between release and recovery points.

Drift cards released at station 4 on July 8, 1953 (fig. 12), were first recovered south of the release point on the west shore of Keweenaw Bay and next on the south shore of the bay. Later recoveries along the south shore of Lake Superior point toward an easterly littoral current in this area as indicated by work of Harrington (1895) and Ruschmeyer, Olson, and Bosch (1957). Subsequent recoveries along the west shore north of the point of release indicate. however, that only a few cards entered this littoral current. This movement verifies the inference of Ruschmeyer, Olson, and Bosch that a fairly well defined current moves south from the tip of the peninsula to the south shore, and that mixing of this current with bay water is limited (their drift bottles moved from the tip of the Keweenaw Peninsula to the south shore but no recoveries were made in Keweenaw Bay). The large number of cards retained within the bay in this study strongly suggest a well defined eddy with a counterclockwise rotation in at least the southern portion of the bay.

Cards released at station 48 on July 3, 1953 (fig. 7), were first recovered 9 days later near the tip of the Keweenaw Peninsula. The short straight-line distance between the points of release and recovery suggests that the cards may have moved in an eddy just southeast of the peninsula's tip for a short time before they were washed ashore. If so, this eddy is probably small and moves in a clockwise direction in conformance with the southward current from the tip of the peninsula (Ruschmeyer, Olson, and Bosch 1957) and the westward movement of water in central Keweenaw Bay (fig. 12) discussed in the preceding paragraph. Subsequent recoveries on all sides of Manitou Island indicate an eddy around the island, and indeed a possible area

of mixing with the littoral current flowing eastward off the tip of the Keweenaw Peninsula. Drift bottles carried in this current have been recovered on this island (Ruschmeyer, Olson, and Bosch 1957). Some drift cards, however, crossed this current and entered the circulation of the open lake to be recovered some 2 months after release on the north and east shore of the lake (fig. 7). These cards may have traveled northeast across the lake, and split into two groups west of Michipicoten Island to give the widely separated recovery locations near Marathon and Michipicoten, Ontario, It is possible, however, that the cards that landed near Michipicoten were part of a group carried in the current flowing south from the tip of the Keweenaw Peninsula and that they moved to their recovery point in the counterclockwise flow of the eastern basin of the lake.

Drift cards were released in the open lake between the Keweenaw Peninsula and Isle Royale at BT cast IV-34 and stations 11 and 49 on July 4 and 7, 1953 (figs. 8, 9, 11). On the dates of release, stations 11 and 49 were outside the littoral current that flows easterly along the north shore of the Keweenaw Peninsula. The recovery of cards from all of those releases exclusively along the north-central shore of the lake reflects a possible counterclockwise circulation within the north-central basin during the period of this study. If the circulation in the central and eastern basins during this period had made up a single massive eddy, as suggested by Harrington's (1895) work, at least some of the drift cards would have been carried into the eastern basin.

Cards released near the tip of the Keweenaw Peninsula (station 49, fig. 8) were apparently influenced by the outer edge of a water mass rotating counterclockwise in the north-central basin. This influence would account for the returns along the northeast shore of the central basin. Cards released with BT cast IV-34 (fig. 9) and at station 11 (fig. 11) appear to have entered this circulation and were more widely dispersed before they came ashore. Earliest recovery dates for both of these releases were nearly the same over the entire area where they came to shore. Recovery dates of cards released with BT cast IV-34 do, however, show a slight progression from east to west.

Drift cards released at station 55 (fig. 10) between Isle Royale and Ontario were recovered on both the north and south shores of the Island, and a good number (12 cards) were recovered 9 days after release on Passage Island just off the northeast tip of Isle Royale. This recovery pattern indicates that the cards moved northeast along the shore of Isle Royale after release. Returns from shore near the point of release can be termed relatively prompt when we consider that the island is only sparsely inhabited by fishermen and tourists during the summer. Recoveries on the southeast shore indicate that at least some of the cards moved around the island in a clockwise direction. Cards that landed on the north shore of Lake Superior adjacent to the southwest end of Isle Royale may have been among those that moved around the island. The cards recovered along the north shore of Lake Superior east of the eastern tip of Isle Royale could have moved around the island or they could have separated from the group circling the island and entered the open-lake circulation before coming to shore. The earliest dates of recovery of these cards from different areas along the north shore suggest a west-to-east drift; the direction of movement indicates that they may have circled the island. This last indication is opposed to that suggested by recoveries of cards released with BT cast IV-34. The areas of recovery do not overlap broadly, however, and recoveries of cards released with BT cast IV-34 were mostly made 2 to 3 weeks later than those of cards released at station 55. The counterclockwise movement of water around Isle Royale is exactly opposite water movements suggested by Harrington (1895).

The known limitations of drift cards as current indicators prohibit their use in speculating too extensively about general patterns of circulation. In fact, some recent work has demonstrated that surface circulation systems of the Great Lakes can change markedly in a relatively short time (Johnson, in press).

EXPLANATION OF TABLES

All data presented in this report are actual measurements—no interpolated values are included.

Values which were obviously incorrect because of instrument failure or human error have been omitted.

Physical

Cruise number. Cruises are indicated by roman numerals (Cruise VI of 1952 and Cruises I-IX of 1953).

Station number. Stations are numbered consecutively (arabic numerals), starting with one at the beginning of the season's operations. The majority of the 1952 stations were not visited in 1953. When a 1952 station was visited in 1953, it was given a new number.

<u>Date.</u> Month, day, and year are given in each table.

Location. The position of any activity is given in degrees, minutes, and seconds of Latitude (north) and Longitude (west) for Cisco records and in degrees and minutes for Williams records.

Time. Eastern standard time at the initiation of bathythermograph cast; when the <u>Cisco</u> stopped for a hydrographic station; or at the beginning of a plankton tow.

Depth. All depths, except those recorded in fathoms by a sonic fathometer, are recorded in meters.

Wind. Cisco records: approximate force is given in descriptive terms; calm, light, Direction is recorded for 8 compass points (table 1). Williams records: force is given in descriptive terms; direction is given for 32 points of the compass; if wind direction changed frequently, it was listed as variable.

Barometer. The barometric pressure, corrected to sea level, is given in inches to two decimal places.

Sky. Cisco records: amount of cloud cover is recorded in descriptive terms; clear, overcast 1/4, overcast 1/2, overcast 3/4, and overcast 1. Cloud type is also recorded. Williams records: coded as as indicated in table 16.

<u>Visibility</u>. <u>Cisco</u> records: visibility is given in descriptive terms (table 1). <u>Williams</u> records: coded as indicated in table 16.

<u>Sea.</u> <u>Cisco</u> records: the approximate amounts of swell and/or waves are given in descriptive terms; calm, gentle, ..., (table 1). <u>Williams</u> records: coded as indicated in table 16.

Secchi disc. The maximum depth at which the Secchi disc was visible is recorded in meters. Actual measurements were made with a chain calibrated in feet.

Bottom. The bottom type as determined from dredge samples is recorded in descriptive terms; silt, mud, clay, sand, gravel, and rock.

Bathythermograph number. Bathythermograph tracings were numbered consecutively (arabic numerals) starting with one at the beginning of each cruise of the Cisco. They were numbered consecutively from the first of the operating season on the Williams.

Temperature. All temperatures are Centigrade and recorded to the nearest 0.1°.

Chemical

pH. Hydrogen-ion concentration expressed as pH values to one decimal place.

Specific conductance. Specific conductance is given in mhos/cm \times 10⁶ at 18° C. ($K_{18} \times 10^6$).

<u>Dissolved oxygen.</u> Values are in parts per million to one decimal place.

Total alkalinity. Values are in parts per million to one decimal place, in terms of calcium carbonate.

<u>Calcium</u>. Values are in parts per million to one decimal place.

Magnesium. Values are in parts per million to one decimal place.

Sodium. Values are in parts per million to nearest 0.05.

Silica. Values are to the nearest part per mil-

Dissolved nitrogen. These values are for ammonia nitrogen, given as parts per million to two decimal places.

Total phosphorous. Values are recorded to the nearest part per billion. Tr means trace.

Biological

Procedures for determination of the following categories are given under the explanation of data.

Wet volume. The wet volume of plankton is given in milliliters per cubic meter to three decimal places. Large organisms occurred in the samples only occasionally so that the volumes represent smaller organisms.

Dry weight. The dry weight of plankton is given in milligrams per cubic meter.

Ash content. Weight of the sample after the organic content has been burned; given in milligrams per cubic meter.

Organic content. Difference between dry weight and ash weight; given in milligrams per cubic meter.
